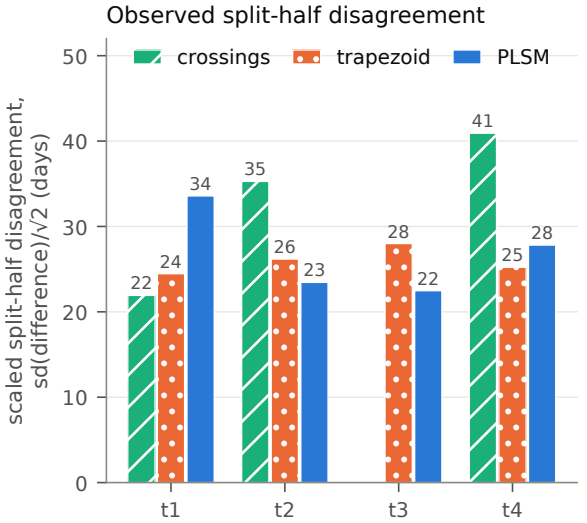
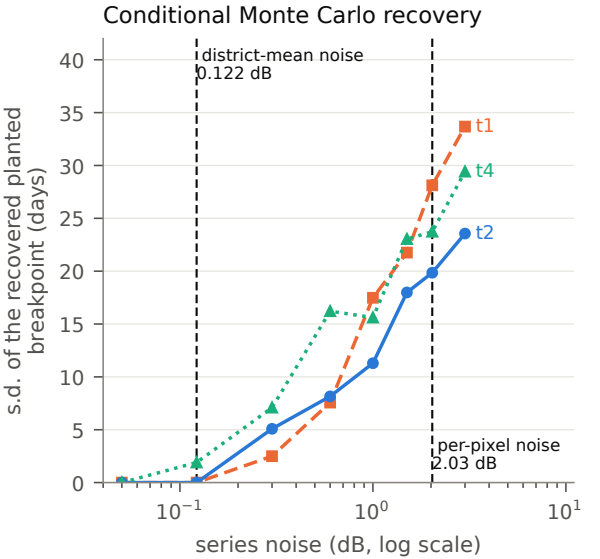
Observed split-half disagreement and conditional Monte Carlo recovery





t1 end of dark phase; t2 end of rise, heading-related; t3 end of plateau, drainage-related; t4 end of fall, harvest-related.
Left: two half-series of one season differenced, per pixel-season -- whatever is common to both halves cancels and is invisible to this statistic.
Right: a synthetic season fitted at each assumed noise level, showing how far the fit lands from the breakpoints it planted. Conditional on that trajectory and that noise; not an accuracy, and not a measurement of the real panel. The two are different quantities and no ratio between them is formed.
